## **I. Introduction and overview**

Bolsa Escola was a conditional cash transfer (CCT) program that offered mothers in poor households a monthly stipend if their children ages 6 to 15 attended school on a regular basis. The program was implemented across all of Brazil between the years 2001 and 2003, until it was folded into the broader Bolsa Familia program (Lindert, 2005). An original feature of the program is that it was decentralized at the municipal level, entrusting the municipality with roles in the selection of beneficiaries and implementation of the transfers. This is in contrast to programs like Oportunidades in Mexico, and the numerous other country programs derived from that experience, that use a centralized approach (Skoufias, 2005). Expectedly, with decentralization, there can be considerable variation in the quality of implementation of the program and the magnitude of its impact on school outcomes according to municipal characteristics, due in particular to elements of local political economy in decision making. Given the great degree of heterogeneity in municipal characteristics, the observed differences in implementation and impact across municipalities provide a unique laboratory for the study of CCT programs when the service provider is a local government.

This paper follows on a 2005 report that analyzed the role of municipalities in implementing the Bolsa Escola program (de Janvry, Finan, Sadoulet, Nelson, Lindert, de la Brière, and Lanjouw, 2005, subsequently referred to as the 2005 Report). The analysis was based on a survey of 261 municipalities in four states of the Northeast. In that report, analysis was conducted at the municipal level, focusing on four municipal roles: beneficiary identification, beneficiary selection, monitoring-verification-enforcement of the school attendance conditionality, and implementation of accountability mechanisms through both a short route via a local council and a long route via electoral rewards on incumbent mayors.<sup>1</sup>

Results reported in the 2005 Report indicated that there was widespread confusion at the local level about the respective roles of the municipality and of the program's central administration in beneficiary selection. As a consequence, beneficiary selection

---

<sup>1</sup> The concepts of short and long route of accountability are developed in the *World Development Report 2004* (World Bank, 2003).

was in some cases done by the municipality, as specified by program rules, and in other cases by Brasilia based on information transmitted by the municipality about indentified potential beneficiaries. The most interesting result in terms of political economy of decentralization in the implementation of a CCT program was that, while direct accountability mechanisms were not always in place, weakening their role, electoral rewards were clearly captured by incumbent mayors when they were perceived as having managed the program more effectively. Mayors were in particular rewarded by voters when they were perceived as having brought a large number of bolsas to the municipality, when they had put a local council into place, and when there was a perception of relatively few leakages of benefits to the non-poor.

In this paper, we take the analysis down to the individual child level, conducting a rigorous analysis of the impact of the program on two aspects that have plagued education in the Northeast: a high drop out rate whereby many school age children start but do not finish the school year; and a high failure rate in making the grade as sanctioned by satisfactory performance during the school year. We use the administrative student records from one or two schools in each municipality over the period 1999 to 2003 to do this analysis. The first two years are prior to initiation of the Bolsa Escola program and the last three during implementation. We then look at the role of municipal factors as they relate to differential levels of impact of the program on these two indicators, relying on the same municipal indicators used in the 2005 Report to characterize municipal features and municipal-level program implementation.

The Bolsa Escola program was first implemented in the Federal District and in the city of Recife, before being scaled up to a national program. Two studies have analyzed these earlier forms of the program. For the Federal District, Abramovay et al. (1998) find that grade promotion rates were eight percentage points higher for beneficiary children compared to children of non-beneficiary families. For the city of Recife, Aguiar, and Araújo (2002) find that drop out rates were 0.4 percent among beneficiaries in 1996 compared to 5.6 percent among non-beneficiary children, a gain of 5.2 percentage points. The studies are, however, not based on comparable treatment and control groups. In both cases, the control group is the population of children based on information from the School Census (World Bank, 2001). While results are of the same order of magnitude as

those which we report here, the programs were somewhat different from the federal program as transfers were higher and conditionalities were weakly enforced. As far as we know, there are no studies that have evaluated the Federal program.

Using a simulation model based on observed child schooling responses to wage based on the PNAD data, Bourguignon, Ferreira, and Leite (2002) provide an ex-ante evaluation of Bolsa Ecola. Their findings suggest that over 50 percent of the children of poor household will respond to the incentives of the program. This implies halving the pre-program drop out rate, again a result not far from our own estimates

By contrast to these studies, the present impact evaluation study of Bolsa Escola is the first to use a rigorous identification of impact based on observed responses to the incentives provided by the CCT.

The general finding of this paper is that Bolsa Escola had a strong impact in reducing child dropout during the school year, securing a 7.8 percentage points improvement in complete year attendance. It, however, did not decrease the grade failure rate, which in fact increased by 0.8 percentage point, expectedly because the transfers helped maintain at school children less able or less motivated in studying that might otherwise have dropped out. The net gain is a 6 percentage points decrease in grade retention, compared to an average grade retention of 26.4%. We also find that a number of municipal features and program implementation practices are strongly correlated to differences in levels of impact of the program on the drop out rate. We find in particular clear evidence that a more transparent beneficiary identification and selection process is associated with higher impact and that expected electoral rewards on incumbent mayors are associated with larger impacts. We also find that stricter enforcement of the conditionality is associated with a higher level of impact on the drop out rate. We are, however, not able to distinguish a distinct role for decentralization vs. centralization in selecting beneficiaries, neither for the presence of a local council on program impact.

The report is organized as follows. In section II, we explain how data were collected on the school performance of children. In Section III, we give descriptive statistics on the drop out rate and the failure rate across municipalities. We explain the empirical methodology used for impact identification and measurement in section IV. We then report in section V results on the impact of Bolsa Escola on dropout rates and grade

promotion. In section VI, we characterize how differences in municipal characteristics and program implementation relate to the program's impact on dropout rates. We conclude in section VII.

## **II. Survey design and implementation**

Data collection took place between October and December of 2004 in 261 municipalities randomly selected across the states of Ceará, Pernambuco, Paraíba, and Rio Grande do Norte. The municipalities of these four states were stratified according to their land inequality, size of public sector, and quota of program beneficiaries; and were randomly sampled from 8 strata. The sample was stratified to capture sufficient variation along variables that may be correlated with governance and electoral practices. Our sample is representative only for these four states and not necessarily for the Northeast as a whole.<sup>2</sup> In each of the 261 municipalities analyzed, two data collection instruments were applied: (1) compilation of school records and (2) a municipal survey.

### **School records**

To properly measure the effect of Bolsa Escola on school attendance and student achievement, we collected in each municipality children's school records for approximately 500 eligible children during the period 1999-2003. To gather these records, two schools were randomly drawn proportionately to the number of Bolsa Escola recipients (data which were obtained from the payments records of the Ministry of Education) within each selected municipality. Information on the grades, enrollment, and grade promotion for each child in the school was collected. In total, we collected administrative records for approximately 293,800 children in primary and secondary school over five years, giving us some 624,059 complete data points.

Drop out and grade failure are recorded in the teachers' annual reports. In these reports, teachers provide the full list of students who started the year, and then indicate,

---

<sup>2</sup> See the 2005 Report for a discussion of the representativeness of these four states for the Northeast along various socio-economic characteristics.

by the end of the year, if a child has passed the grade, failed the grade, transferred to another school, dropped out of school, or died.

Although administrative records are presumably more accurate than self-reported information on attendance and grade promotion, not having conducted household interviews resulted in at least two important shortcomings. First, we do not have information on children and household characteristics. And while the use of child fixed-effects eliminates any biases associated with our inability to control for time invariant characteristic of the child and his family, it does prevent us from exploring how the impacts vary according to these demographic characteristics. Moreover, we unfortunately cannot investigate whether the program was targeted according to certain observable characteristics of children, other than their initial attendance or achievement status.<sup>3</sup> Secondly, we cannot follow children who transfer out of the school. However, we can observe if the child transferred to another school (as opposed to being reported as missing school), and we fortunately observe that less than four percent of the children had transferred. In the analysis that follows, we simply remove these children from the sample.

### **Municipal survey**

The municipal survey consisted of several parts designed to gather general information on municipal governance, public administration, and implementation of the Bolsa Escola program. Respondents on the various sections of the questionnaire were mostly public administrators, but also included politicians and key members of civil society, such as the local priest or president of the labor union. An important objective of the survey was to characterize the major stakeholders in the provision of public goods and government programs, and how these goods and services were allocated.

For questions on Bolsa Escola, we interviewed the respective program coordinator about how the municipality identified and selected beneficiaries, and imposed and monitored the conditionalities. We also gathered information to assess how transparent the program was in its implementation. For the questions on the Bolsa Escola

---

<sup>3</sup> These two problems could be solved with access to the Cadastro Unico records for the corresponding households. For a discussion of Cadastro Unico, see de la Brière and Lindert (2003).

council, a council member (priority was given to non-governmental members) was asked several questions about the composition of the council and its level of activity.

In sum, four field teams, one in each state, assembled a unique database comprised of municipal information on 261 municipalities, and comprehensive school records for over 293,800 eligible children spanning the years 1999-2003.

### **III. School records information on drop out and failure rates**

In this section, we provide some basic descriptive statistics on the administrative data that were collected. Absent standardized test scores, the focus of this study is on dropout rates and failure rates.

#### **Dropout rates**

Figure 1 depicts the distribution of dropout rates across municipalities, by beneficiary status and year. The plots in the first row show the dropout rates among children who did not receive Bolsa Escola, and the plots in the second row are the dropout rates among children who received Bolsa Escola. The last row computes the difference in drop out rates between program recipients and non-recipients.

Figure 1 suggests that municipalities on average targeted the program to children who were less likely to drop out of school based on their pre-program performance. Before the start the program in 1999-2000, dropout rates among beneficiary children are on average only 4.5 percent compared to 17 percent among children who did not participate in the program (see Appendix Table). In fact, 95 percent of the municipalities have lower dropout rates among program recipients than non-program recipients during both the treatment years (2001-2003) and the pretreatment years (1999-2000), and only 13 percent of the municipalities had differences in pre-program dropout rates between treatment and control groups that were not statistically different from one another.

### **Failure rates**

Figure 2 presents a similar set of distributions as those depicted in Figure 1, but for failure rates. These distributions are based on the sample of children that did not dropout of school, since this would automatically result in a failure.

Unlike with dropout rates, failure rates are larger among beneficiaries (14 percent) than among non-beneficiaries (12.1 percent) (see Appendix Table). However, while significant, this difference is small. In fact, whereas pre-program dropout rates were similar between treatment and control groups in only 13 percent of the municipalities, pre-program failure rates are similar in over 67 percent of the municipalities. This figure suggests that, conditional on attending school, the program was targeted toward children with slightly higher failure rates.

### **Implications for targeting**

We conclude this inspection of descriptive statistics by noting that the program was not targeted toward the more problematic children in terms of prior histories of dropping out. To the contrary, the program was targeted at the better performing students in terms of propensity of dropping out. This has two implications for the subsequent analysis. One is that we need to proceed by double difference as opposed to a simple difference analysis as there was clear selection between treated and non-treated groups. This is precisely what our panel data with pre- and post-program observations allow us to do. The other is that the magnitude of program impact will expectedly be diminished by positive selection, since the program differentially targeted children that were already more likely to meet the enrollment continuity objective. This is different from targeting CCT for maximum effect of the conditionality as has been explored with the Progresá experience (de Janvry and Sadoulet, 2006).

## **IV. Empirical Methodology**

We analyze two aspects of the Bolsa Escola program. Our first objective is to measure the impact of Bolsa Escola on two dimensions of educational achievement – dropout and grade retention rates – by municipality. Given the non-experimental design

of the program, credible estimates of the program's impact will depend on the internal validity of the research design. In this section, we propose an identification strategy to measure the effects of Bolsa Escola. This method relies on the analysis of schools' administrative records, which provide panel data on children before and after the start of the program to estimate the program's impact for each municipality.

Having estimated the impact of the program by municipality, our second objective is to measure how municipal-level characteristics and municipality behavior toward program implementation relate to the program's impact. Because the municipality is responsible for selecting program beneficiaries, the program becomes an instrument to maximize the municipality's own socio-political objectives, which could lead to substantial variation in the program's impact across municipalities. In this second stage, we will consequently associate municipal-level characteristics and behavior – such as poverty and inequality levels, political affiliations, quality of governance, administrative structure, transparency of the selection process, electoral cycle, and presence of a social council – with the impact of the program.

### **First-stage Estimation**

The empirical approach used to estimate the impact of Bolsa Escola on schooling outcomes (dropout and grade retention rates) can be formalized in the following regression model. For an individual child  $i$  in municipality  $j$ , let  $S_{ijt}^0$  denote a schooling outcome in period  $t$  without a program (superscript 0). The individual  $i$  is observed in time period  $t$  and has characteristics that make him belong to a group  $B_{ij} \in \{0,1\}$ , where a one denotes beneficiary in the Bolsa Escola program. Our universe consists of all the children that were deemed eligible by the general criteria of the program. Among these eligible children, the municipality selected which children will receive the transfer, given its fixed allotment of stipends. The children who qualified for the program, but were not selected by the municipality, serve as our control group. Eligibility characteristics are children ages 6-15 years old, currently enrolled in primary or secondary school, and whose family's monthly income is no more than R\$90 per capita. In the absence of the Bolsa Escola program, the schooling outcome for child  $i$ , is

$$S_{ijt}^0 = \alpha + \beta_t + \eta B_{ij} + \varepsilon_{ijt}, \quad (1)$$

where  $\beta_t$  represents a time fixed effect,  $\eta$  is the effect of program eligibility, and  $\varepsilon_{ijt}$  is a random error term.

With the program (superscript 1), the schooling outcome becomes:

$$S_{ijt}^1 = \alpha + \beta_t + \eta B_{ij} + \theta_{jt} + \varepsilon_{ijt},$$

where  $\theta_{jt}$  measures the program impact on eligible children in municipality  $j$  at time  $t$ .

Combining these two expressions gives schooling outcomes as:

$$\begin{aligned} S_{ijt} &= P_{ijt} S_{ijt}^1 + (1 - P_{ijt}) S_{ijt}^0 \\ &= \alpha + \beta_t + \eta B_{ij} + \theta_{jt} P_{ijt} + \varepsilon_{ijt}, \end{aligned} \quad (2)$$

where  $P_{ijt} = B_{ij} T_t$  is an indicator for if the child did in fact participate in the program,  $T_t = 1$  for  $t \geq t_0$ , and  $t_0$  is the date of introduction of the program.<sup>4</sup> The last equality follows from the common assumption that the effect of the program  $\theta_{jt} = S_{ijt}^1 - S_{ijt}^0$  is constant across individuals, measuring the average municipal program impact. Note that with repeated observations per child, we can generalize this model to allow for individual-specific fixed effects that are potentially correlated with whether the child participates in the Bolsa Escola program or not. The equation to be estimated thus becomes:

$$S_{ijt} = \alpha + \beta_t + \phi_{ij} + \theta_{jt} P_{ijt} + \varepsilon_{ijt}, \quad (2')$$

where  $\phi_{ij}$  is a child fixed effect.

It is important to emphasize that the parameter  $\theta_{jt}$  is identified by comparing changes in the schooling outcomes of beneficiaries to non-beneficiaries over time, among the children that were all eligible. With this approach, we estimate not only an impact for each municipality but, depending on the number of years of post-treatment data, several yearly treatment effects. Another key aspect of this approach is the fact that we now have repeated observations on a single child. This will allow us to control for the non-random selection of children who received the program (as confirmed by inspection of the

---

<sup>4</sup> There is virtually no distinction between participating in the program and being offered the program because take-up rates are 100 percent.

descriptive statistics), which may otherwise bias the treatment effect parameter. This method requires a fairly reasonable counterfactual assumption, namely  $E[\varepsilon_{ijt} | P_{ijt}] = 0$ , i.e., that in the absence of the program differences in schooling outcomes over time would be the same for those who have received the program and those who qualified for the program but did not receive it. Employing individual fixed-effects increases the plausibility of this assumption.

### **Second-stage estimation**

Given the decentralized design of the program, one can expect considerable variation in the impact of the program across municipalities. To understand features of contexts under which the program performs more efficiently, the second stage of the analysis will consist in associating various municipal-level characteristics  $z_j$  to the program's impact. Our empirical strategy can be formalized as follows. Assuming that  $\mu_j$  is a random disturbance term, we can regress the following model:

$$\bar{\theta}_j = \lambda + \delta z_j + \mu_j, \quad (3)$$

where  $\bar{\theta}_j$  is the average impact of the program in municipality  $j$ . The coefficients  $\delta$  indicate how municipal characteristics relate to the impact of the program. These characteristics may include measures such as the degree of electoral competition, political accountability, inequality of income and land, and various school characteristics. Contrary to equations 2 and 2', these equations (3) are not causal: they measure partial correlations between program impact and municipal features.

## **V. The impact of Bolsa Escola on dropout rates and grade promotion**

### **The average impact of Bolsa Escola on dropout rates**

Table 1 presents regression results from estimating several variants to the difference-in-difference model in equations 2 and 2'. The dependent variable in each of these regressions is a binary variable, which assumes a value of one if the child drops out of school during the school year. Column (1) presents the basic OLS estimates of the impact of Bolsa Escola on dropout rates, without controlling for individual fixed effects

(equation 2). A causal interpretation of these estimates would suggest that Bolsa Escola actually *increased* dropout among beneficiary children by 1.7 percentage points. However, given the 12.6 percentage difference in pretreatment dropout behavior between treatment and control children, there are several reasons why this naïve estimate might be biased. If, for instance, program officials targeted the program to children relatively more at risk of dropping out of school, then this would make the measurement less negative or even positive. Similarly, if the program rewarded children who were already attending school (for having received some positive shock), then reversion to the mean would suggest a less negative or even a positive impact.

Column (2) presents the estimate of the treatment effect, after controlling for the child's initial dropout status the year before introduction of the Bolsa Escola program. The estimated treatment effect suggests in fact that Bolsa Escola did *reduce* dropout rates by at least 3.4 percentage points. Column (3) presents estimates of the treatment effect that includes individual fixed-effects (equation 2'). This model not only controls for the pre-treatment dropout status of the child (thus incorporating the previous specification), but also for individual characteristics that are time invariant such as gender, and certain household and community characteristics. Under this specification, Bolsa Escola reduced dropout rates among beneficiary children by 5.6 percentage points.

Our most general specification is presented in column (4). This specification extends the fixed-effects model to allow for children with different pre-treatment dropout status to have different year effects. This accounts for a possibly fundamentally different pattern of behavior over time for these two types of children. Identification is then based upon comparison of the change in dropout level between the treated children and their counterparts of the same type. The estimate presented in this model suggests that Bolsa Escola reduced dropout rates by 7.8 percentage points.

Even though the model presented in column (4) is quite flexible, the substantial difference in pretreatment dropout status between recipients and non-recipients is still cause for concern. One possible robustness test is to estimate the impact of the program only among the 13 percent of the municipalities where the pre-treatment dropout status was not statistically different between program recipient and non-recipients. Columns (5) and (6) present the estimation results for this restricted sample of municipalities. The

estimates for both the OLS model and the fixed-effects model are highly consistent with those presented in column (4).

Table 2 explores whether the program had a differential impact according to the type of class, the grade level, and over time. As seen in columns 1 to 3, the program had a larger impact on beneficiary children enrolled during the night classes – classes which tend to be for older and less able children –, reducing their dropout rates by 13.3 percentage points. Program impacts were equally large both when comparing primary versus secondary school children, and over the years of program implementation. The difference in the program's impact between 2001 and 2002 is only 1.2 percentage points and 0.5 percentage points for 2002 and 2003.

### **The average impact of Bolsa Escola on failure rates**

Table 3 reports the estimates of the impact of Bolsa Escola on the likelihood that a child fails the grade. The estimates reported are based on specifications similar to those presented in Table 2. The estimation sample has been restricted to the set of children that have not dropped out (since this results in an automatic failure). The results should thus properly be read as probability of failure, conditional on not having dropped out of school. Because the sample of children that are in school is itself affected by the program, one should be careful in interpreting the impact of Bolsa Escola on the failure rate. It combines the direct effect of Bolsa Escola on the probability that a particular child would fail his grade and the indirect effect through the composition of the children population that does not drop out. Hence, even in absence of any direct effect, one could observe an impact on the average failure rate, strictly from the compositional effect.

The results presented in Table 3 suggest that Bolsa Escola may have actually increased the failure rate. The estimates for our most general specification (see column 4) indicate that Bolsa Escola increased the likelihood of failing a grade by 0.8 percentage points, which represents 5.7 percent over the average value of 13.1 percentage points.

Table 4 examines how the effect of Bolsa Escola on failure rates differs according to the type of class, grade level, and over time. This perverse effect of Bolsa Escola appears to be the result of beneficiaries in the night class. Although the estimate is not statistically significant, the magnitude is relatively large. And as seen in columns 4 and 5,

most of the effect is concentrated in the primary school, and in the second and third years of the program.

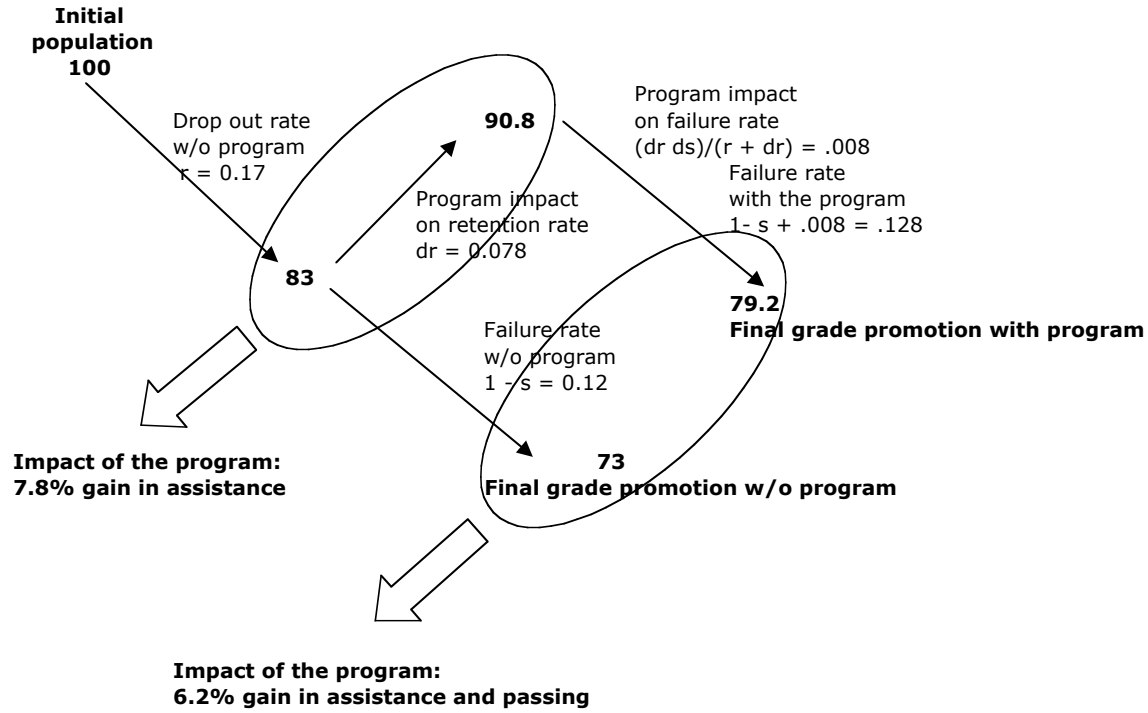

This result on failure rates is in a sense not surprising of the attendance-achievement trade-off that can be induced by a CCT program. The CCT effect induced parents to keep at school children that would otherwise have dropped out. The increase in grade failure is consistent with the idea that Bolsa Escola may have brought in or maintained at school children with lower academic aptitude or that were less motivated to succeed than those who stayed in school without a transfer.

### **The overall impact of Bolsa Escola on grade promotion**

Ultimately, the objective of the program is to increase the human capital of the beneficiary population. Thus, the success of the program depends not only in keeping children in school but also in insuring that they successfully pass their grade. In Table 5, we analyze the impact of the Bolsa Escola program on grade promotion. This is done with a reduced-form regression of the overall grade retention, which is defined as either dropping out or failing the grade for those that did not drop out. We find (column 4) that this joint effect is a decrease of 6 percentage points in the grade retention rate, compared to the average value of 23 percentage points. While this is a substantial achievement, there is still a long way to go to a well performing school system. The increase in failure rate is thus responsible for a loss of 1.8 of the 7.8 percent gain in keeping children in school.

A quick calculation using pre-program drop out and failure rates in the Appendix Table, confirm this large decline in grade promotion. Without the program the combination of an attendance rate of 83% (dropout rate of 17%) and a conditional success rate of 88% (failure rate of 12%) gave a grade promotion rate of 73%. With the program, the attendance rate is higher, rising to 90.8%, but the conditional success rate is slightly lower, at 87.2%, leading to a grade promotion rate of 79.2%. This is the 6 percentage points increase estimated in the combined regression reported in Table 5.

Results can be summarized in the following Figure 3 where we start from a pre-program group of 100 eligible children. In the end, the effect of the program on attendance is 7.8% while the net effect of the program on grade promotion is 6.2%.

**Figure 3. Impact of the program on school attendance and grade promotion**

A hypothetical but interesting exercise consists in computing what the failure rate of the children that are kept in school by the program would have to be if the program had no direct effect on the failure rate of the other children. Let  $r$  denote the attendance rate without the program. We assume that these children have a conditional success rate  $s$ , independent of whether there is or not a program. The program increases the attendance rate by  $dr$ , with children that we assume have a success rate of  $s - ds$ . The average success rate with the program is thus:

$$\frac{rs + dr(s - ds)}{r + dr} = s - \frac{drds}{r + dr}.$$

We estimated the impact on the attendance rate to be  $dr = .078$  (Table 2, col. 4) and on the conditional failure rate to be  $\frac{drds}{r + dr} = .008$  (Table 3, col. 4). Hence, for the children that are kept in school by the program, the differential failure rate is:

$$ds = .008 \frac{r + dr}{dr} = 0.094.$$

This means that, if the failure rate in the student population that comes to school even without the program remained at the pre-program value of 13%, it is as high as 22.4% for the children that are kept in school by the program. If, however, the presence of these children implies a worsening of school conditions for all and an increase in failure rate of the other children, then the difference between the two groups of children could be lower. By the same token, if the conditionality on assistance of Bolsa Escola improves the passing rate of the children that would go to school (but possibly with less regularity) without program, then it implies that the failing rate of the children retained in school by the program would be even higher. In any case, this suggests a need for complementary actions that would ensure a successful grade passing performance for the children that are maintained in school by the program.

### **The distribution of impacts of Bolsa Escola on dropout and failure rates**

As discussed above, the Bolsa Escola program reduced dropout rates by 7.8 percentage points on average. However, given the program's decentralized design there is expectedly considerable variation in the program's impact across municipalities. Fortunately, our survey design allows us to estimate an impact of the program on both dropout and failure rates for each municipality in the sample. Figure 4 presents the distribution of estimated impacts of the program on dropout rates using the econometric specification presented in column 4 of Table 1. The distribution of impacts is skewed towards negative values with a median impact of 6.7 percentage points. While the impacts range from -25.5 to 10.7 percentage points, over 95 percent of the impacts are in fact negative and few positive impacts are measured precisely.<sup>5</sup> In addition to the distribution of unbiased estimates of the impact, Figure 4 also plots the absolute value of corresponding t-statistic. Over 55 percent of the estimates are significantly negative at a 95 percent confidence level and 65 percent at a 90 percent confidence level.

Figure 5 presents the distribution of impacts on failure rates using the econometric specification in column 4 of Table 3. The distribution is only slightly skewed towards the positive values, but otherwise fairly symmetric. The median impact is -0.2 percentage

---

<sup>5</sup> As can be seen in Figure 4, only one is measured at 90 percent confidence level and the rest have an average t-statistics of 0.80.

points, and the range of the impacts goes from  $-14.4$  to  $20.5$  percentage points. Unlike the previous distribution, only 10 percent of these impacts are significantly different from zero, and they lie mostly at the positive tail of the distribution.

## **VI. Are the program's impact on dropout rates related to municipal characteristics and to municipal program implementation procedures?**

There are at least three reasons why the effects of the program might vary across municipalities (Hotz, Imbens, and Mortimer, 2006). First, the distribution of children's characteristics associated with program efficacy may differ across municipalities. For example, if children with more highly educated parents respond better to the program than children with less educated parents, then a municipality with a larger proportion of school-aged children with higher educated parents may achieve a greater impact. Thus, even if each municipality targeted and implemented the program in the same manner, differences in contextual factors would create differential effects of the program.

Second, even if the population of eligible children was identical across municipalities (or we could condition perfectly on these differences in contextual variables), municipalities may want to target different subpopulations according to their own socio-economic and political objectives or constraints, thus creating differential effects. How a municipality identifies and selects beneficiaries will ultimately affect which subgroups receive treatment and consequently the impact of the program.

Third, the municipalities, while offering the same treatment, may differ in the manner in which they operate the program. Because Bolsa Escola is a conditional cash transfer program, differences in how a municipality monitors and enforces the program requirements may have important consequences for the effects of the program.

In this section, we examine how differences in the way a municipality identifies and selects its beneficiaries, and enforces and monitors the program requirements, are correlated with the program's effect on reducing dropout rates. However, before doing so, we investigate in Table 6 the extent to which contextual characteristics of a municipality are associated with program impacts.

Table 6 presents the estimation results of equation 3 that regresses Bolsa Escola's impact in a particular municipality on various characteristics of the mayor and the municipality. Column 1 presents the base specification, which includes the basic socio-economic characteristics of the municipality such as per capita income, population density, share of rural households, and income inequality. Various sets of other municipal and mayor characteristics are sequentially added in each column, such that column 5 presents the most general specification which includes all the municipal and mayor characteristics, as well as state fixed-effects.

Despite the variation in impacts across municipalities, few municipal and mayor characteristics explain much of this variation. The base specification explains only 7 percent of the variation. And while per capita income appears to be a strong predictor of impact, much of this variation is driven by state-level variation. Controlling for state fixed-effects, the negative correlation between income and impacts diminishes substantially and become no longer statistically significant.

The gender of the mayor and the mayor's term are robust to the inclusion of state fixed effects. The program performed 3.3 percentage points better in municipalities with a male mayor, but 1.7 percentage points worst among second-term mayors, both of which are large effects. These mayors cannot be re-elected, and long route of accountability effects via political rewards are consequently not operative on them, possibly explaining this deterioration in performance. First term mayors are conversely associated with a better program impact performance, lending support to the effectiveness of a long route of social accountability. There is, however, no evidence that a municipality's level of patronage or clientelism, as perceived by survey respondents, is associated with the program's impact. It also appears that whether the municipality received training on how to register the beneficiaries did not have an effect on impacts.

### **Beneficiary identification**

As documented in the 2005 Report, public administrators and school teachers were mostly responsible for identifying the beneficiary population. Health agents and members of civil society – such as NGOs, municipal councils, and civil society

volunteers – played a much more limited role, participating in only 32 and 11 percent of the municipalities, respectively.

Consequently, most of the registration process took place in public locations, with either schools (85 percent) or the mayor’s office (55 percent) providing the natural setting. Only 28 percent of all municipalities in the sample registered individuals at their home, and among these municipalities, the median percentage of households interviewed was 20 percent. Moreover, only approximately 38 percent of the municipalities used some form of geographical targeting to decide in which areas to begin the registration. Among those municipalities that did prioritize specific areas, 62 percent targeted the poorest neighborhoods, although other considerations that mattered included the number of schools in an area, ease of access to the region, and the rural nature of a community.

Schools also performed the function of announcing the program to the community, with 94 percent of the municipalities using schools to notify individuals about the program. Schools, however, were not the only source of information about the program, as it was also advertised on the radio (66 percent) and in public announcements (53 percent).

In Table 7, we investigate the extent to which these different approaches to registering program beneficiaries are correlated to program’s impact on dropout rates. The estimation results presented in each column are slight variants of the model specified in equation 3, and each specification controls for the full set of mayor and municipal characteristics presented in Table 6, along with state fixed-effects.

Column 1 presents the association between who registered the pool of eligible children and program impacts. The use of teachers, health agents, or members of civil society are not correlated with program impacts, but municipalities that relied on public administrators from the mayor’s office to register its beneficiary population did experience a sizeable reduction in program performance. The use of public administrators is associated with a 2.4 percentage point increase in program impacts, which implies a 33 percent reduction in the program’s impact on dropout rates. Registration by members of the mayor’s office as opposed to teachers, health agents, and civilian volunteers can be associated with less transparency in enlisting beneficiaries, and hence in a lower level of program impact on school assistance.

While the use of teachers may not have affected the effectiveness of the program, registering the beneficiaries at the school did have a beneficial effect, correlating with a 2 percent points higher impact (see column 2). Municipalities that also registered beneficiaries in the communities also had a slightly larger impact of about 1.1 percentage points, although this estimate is only measured at 87 percent confidence. We also find no evidence that the municipalities that targeted the registration process geographically or conducted home visits improved the program's effectiveness (see column 3). However, the program's impact on dropout rates is 2 percentage points lower in municipalities that verified the information provided in the registration process.

Column 4 investigates whether differences in how beneficiaries were notified about the registration process is related to the program's effect on dropout rates. As documented in the 2005 Report, it appeared that the registration process was well advertised, which mostly explains why the different approaches to announcing the registration process is not associated with program impacts. Column 5 presents a regression where these different decisions are estimated jointly, and we find that the results are robust.

### **Beneficiary selection**

One of the more striking findings reported in the 2005 Report was the extent of confusion surrounding the municipality's role in the selection process. Even after accounting for the possibility that a municipality may have indirectly selected its beneficiaries in the registration process, at least 40 percent of the municipalities did not knowingly select their program recipients. Whether this misunderstanding of the selection process is correlated with program impacts is investigated in Figure 6.

The figure depicts the distribution of impacts on drop out rates, by whether or not the municipalities selected their beneficiaries. Compared to the distribution of impacts for municipalities that did select their beneficiaries, the distribution of impacts for municipalities that did not selected their beneficiaries is shifted slightly to the left, but with a fatter tail on positive impacts. When the comparison is made in a regression framework to control for mayor and municipal characteristics, we see in column 1 of

Table 8 that on average there is only a 0.4 percentage point difference, and that it is not statistically different from zero.

That the program's impact was not associated with whether the municipality selected its beneficiaries can be interpreted in several ways. One possible interpretation is that decentralized targeting is as effective as centralized targeting, or at least that the advantages and disadvantages of decentralized targeting relative to centralized targeting (i.e., better information but greater risk of capture) cancel out.

In columns 2 to 4 of Table 8, we investigate various aspects of the selection process among the municipalities that did actively select their beneficiaries. In column 2, we find that the mayor's involvement in the selection process is not correlated with program impacts, despite evidence that the mayor's involvement in beneficiary selection is correlated with higher levels of clientelism (see the 2005 Report). In column 3, we see that targeting on household income does not necessarily improve program impacts but that targeting on the number of children do. Hence, the incentive effect of CCT on staying at school appears to be most beneficial for children in large families.

How the municipality disclosed the list of beneficiary is only weakly related to the impacts of the program. As seen in column 4, municipalities that used town-hall meetings to announce the beneficiaries are associated with only slightly better outcomes (at 88 percent confidence), supporting again the positive role of greater transparency on program outcomes.

### **Monitoring and enforcement of conditionalities**

Participants to the Bolsa Escola program receive monthly payments conditional on attending at least 85 percent of their classes. Even though this is the only requirement imposed by the federal government, some municipalities imposed other conditions upon the parents: requiring them to attend school meetings or to help maintain and clean the school. Overall 32 percent of the municipalities imposed at least 2 requirements for program participation.

Conditions of the program are not strictly enforced, as municipalities have little incentive to monitor these participation requirements in a meaningful manner or are using the transfers to achieve other goals than educational gains for the children of recipient

households. When asked what consequences students would incur for not complying with the school attendance requirement for 3 consecutive months, 71 percent of the municipalities responded that nothing would happen if the family could justify the absences. In 72 percent of the municipalities, program coordinators indicated that the household would have their payments suspended for an average of 2 months, but only 27 percent claimed that the child would be cut from the program (2005 Report).

Table 9 examines whether the number of conditionalities imposed or how the municipality dealt with non-compliance are associated with program impacts. When we examine the types of penalties that the municipality imposes we do see that those who do enforce non-attendance by loss of the CCT do see better impacts (see column 2), suggesting that the conditionality may be an important aspect of the impact. By contrast, municipalities that send program officials to the non-compliant child's house do have worst impacts. Hence, in the debate on whether to condition transfers or not in securing larger program impacts on child human capital (Schady and Araujo, 2006), results obtained here support the proposition that threat of loss of benefits can indeed be effective in enhancing program impacts.

### **Bolsa Escola's social council: oversight and appeals**

To participate in the Bolsa Escola program, a municipality was required to create a social council (*Conselho de Controle Social*) designed to approve the list of selected families, verify the school attendance of beneficiary children, and address complaints about the program. Moreover, in further stipulating that at least 50 percent of the council be comprised of non-governmental members, the council was to provide program oversight and voice for the various segments of civil society.

A result reported in the 2005 Report is that councils were not operational in many municipalities. The observation that they met at least once a month in only 38 percent of the municipalities perhaps best describes their lack of functionality. Another stark observation is that only 54 percent of the councils maintained an updated list of the beneficiaries.

In Table 10, we examine how various aspects of Bolsa Escola's social council are associated with the program's impact on drop out rates. The results reported suggest that

social council did not have any significant effect on program impacts. Whether or not the council existed, functioned, or was active in the process has virtual no predictive power in explaining the variation in program impacts. This result is surprising and disappointing. It signals, however, that the short route of social accountability, that can expectedly be more expedient than the long route via rewards in electoral cycles, was not operative on program impacts.

## **VII. Conclusions**

Bolsa Escola was one of the largest conditional cash transfer (CCT) programs in the world, only second in rank to Mexico's Oportunidades program (Rawlings and Rubio, 2005). It had the unique characteristic of being decentralized at the municipal level, with local authorities in charge of beneficiary identification and selection and of program implementation. Yet, while many impact evaluations are available for Oportunidades, no similar evaluation is yet available for Bolsa Escola. This paper uses a large survey conducted in 261 municipalities of the Northeast and school records collected for 293,500 children over a five years period bracketing introduction of the Bolsa Escola program to provide a rigorous impact evaluation of the program. Specifically, we analyze, in a first stage, the impact of the transfers on school drop out, grade failures, and grade promotion at the child level. In a second stage, we analyze how municipal characteristics and municipal performance in program implementation are associated with the level of program impact in each municipality.

Results show that the bolsas were not targeted at children with lower pre-program performance in school attendance. The possibility of better targeting the CCT on children at risk of dropping out of school thus leaves room for increasing the impact of the program on schooling. In spite of this, we find that the CCT had a very strong impact on continuity in school attendance, inducing an 7.8 percentage points decline in drop out. This impact was equally large in primary as in secondary school, and across the three years of program implementation, and was larger in the more difficult night shift, typically with older and less able students, than in the morning and afternoon classes. Not surprisingly, we find that the program worsened the failure rate, which increased by

0.8 percentage point. This effect was larger in primary school and in the last two years of program implementation. This can be attributed to the fact that the cash incentive helped retain at school less able and motivated children that would otherwise have dropped out. The large positive school assistance effect was thus met by a small negative grade failure effect. The joint effect of the program in reducing drop out or grade failure is an important 6 percentage points gain in grade promotion. While a sign of success, it still leaves 21% of the children selected for Bolsa Escola either dropping out of school or failing the grade. Hence, in spite of this success, room for improvement remains, in particular on the supply side of schooling in helping retain more children and helping those who were retained by the transfer be more successful in passing the grade.

Partial correlations between municipal features and magnitude of program impact on drop out rates are revealing of municipal characteristics and management practices that favor a larger impact. Most importantly, we repeatedly found that features that favor transparency in program implementation (procedures followed for the identification and selection of beneficiaries) are associated with larger program impact. This includes the registration of beneficiaries by teachers, health agents, and civilian volunteers as opposed to by members of the mayor's staff, registration in more public places such as the school, verification of the information provided in the registration process, and divulgation of the list of beneficiaries in town hall meetings. We also found that enforcement of the school attendance conditionality via threat of loss of benefits is strongly associated with a larger impact on continuity of enrollment. Conditioning the cash transfers thus appears to be efficient for child schooling. Finally, we observed, as we had done in the 2005 Report, that the long route of social accountability is effective as first term mayors have a superior performance with the program compared to second term mayors that cannot run for re-election. On the negative side, we found that decentralized identification of beneficiaries did not lead to program impact any different than centralized identification, but did not perform worst either, suggesting a wash between the information gains and the capture costs typically associated with decentralization. And we also found that the short route of social accountability via local social councils had no significant relation with performance.

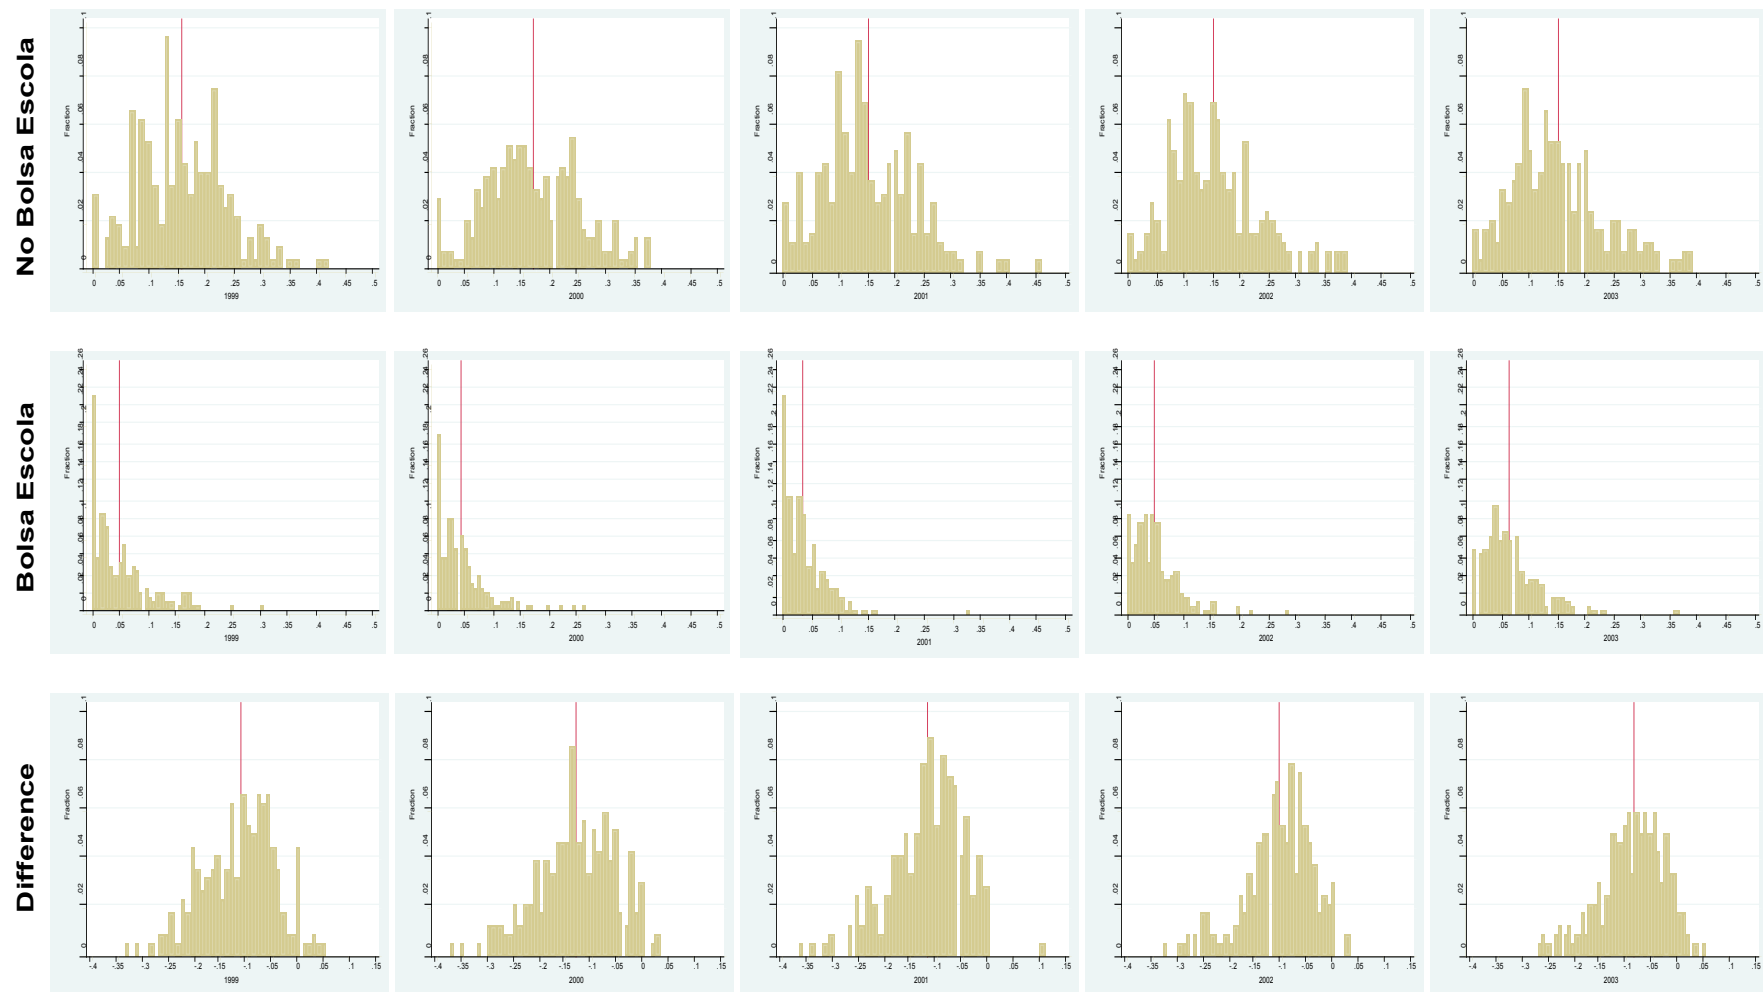

These results on early steps toward decentralized implementation of CCT programs are encouraging. They show positive impact on the main goal pursued by the CCT, namely greater continuity in school attendance. They suggest the importance of conditioning transfers in achieving impact. And they also suggest the key roles of transparency and democratic rewards in enhancing the magnitude of impacts. They, however, also show that progress remains to be made in targeting transfers for maximum impact of the conditionality, in capitalizing on the potential gains from decentralization for greater program efficiency, and in mobilizing civil society to attain greater accountability through a short route between service providers and beneficiaries.
